Differential expression of disialic acids in the
cerebellum of senile mice.

Running title: Disialic acids in central nervous system

Keywords: brain / cerebellum / disialic acid / senile/ ST8Sia III.

ABSTRACT

It is known that disialic acids (diSia) are present in the mammalian brain. However, the precise anatomical distribution and the chronology of its expression along life are not well studied yet. It is accepted that the transfer of disialic acids in the brain is mediated mainly by the enzyme ST8Sia III \( (\alpha 2,8\text{-sialyltransferase III}) \). We studied the expression of diSia glycoepitopes and of the ST8Sia III gene in different structures of the mouse brain at different postnatal stages by immunohistochemistry and real-time PCR, respectively.

C57BL/6 mice of different stages were used. Samples of hippocampus, olfactory bulb, cortex and cerebellum were processed for studies of molecular biology and immunohistochemistry.

Histological analysis revealed an important decrease in diSia labeling in the senile cerebellum compared to other structures and stages \( (p<0.001) \). In concordance with these results, a significant decrease in ST8Sia III gene expression was found in the cerebellum of senile animals \( (p<0.001) \). These results suggest that disialic acids are constantly expressed but with differential expression in various areas of the mouse central nervous system. On the other hand, the concordance in the decreased expression of ST8Sia III and the diSia epitope in the cerebellum of senile animals suggest a role of diSia in this structure or, inversely, an influence of aging on the expression of diSia in the cerebellum. Further research in that direction could elucidate the roles of disialic acids in brain function in health and disease.
INTRODUCTION

Sialic acids (SA) are commonly present as monosialyl residues at the non-reducing terminal end of glycoconjugates. Polysialic acid (PSA), one of the best known forms of SA, is attached to the neural cell adhesion molecule (NCAM) (Angata et al, 2000). PSA promote changes in cell interactions and thereby facilitate changes related to neuroplasticity in the structure and function of the nervous system. (Rutishauser and Landmesser, 1996; Seki and Rutishauser, 1998).

In some cases, α2,8-linked sialic acid chains with 2 or 3 sialic acid residues are linked to gangliosides, and are involved in various biological processes, such as cell adhesion, cell differentiation, signal transduction, and surface expression of stage specific antigen (Schauer et al, 1996; Angata and Varki, 2002).

It was previously demonstrated that α2,8-linked disialic acid (diSia), as well as trisialic acids structures, occur in several glycoproteins in the mammalian brain (Sato et al, 2000; Inoko et al, 2010). NCAM from adult mice are sialic acid-containing glycoproteins. The physiological function and the specific anatomical distribution of those epitopes is not completely understood. However, based on in vitro studies, it is accepted that the diSia epitope is involved in neurite formation (Sato et al, 2002). Specifically, it was demonstrated that retinoic acid treatment increases the diSia epitope on the 100-kDa glycoprotein CD166, a cell adhesion molecule involved in neurite extension (Sato et al, 2002). In addition, it was demonstrated that the α2,8-sialyltransferase ST8Sia III enzyme is responsible for the formation of the diSia epitope on CD166 (Sato et al, 2002). ST8Sia III synthesizes disialic acids from monosialylated glycoproteins and glycolipids (Yoshida et al, 1995), and might be important in the formation of the disialic acid glycotope on glycoproteins and glycolipids. Other sialyltransferases are involved in disialic acid synthesis: ST8Sia VI is shown to synthesize the disialic acid structure on O-linked glycan chains in glycoproteins (Takashima et al, 2002). Furthermore, it was demonstrated that ST8Sia I is responsible
for disialic acid formation on glycolipids (Watanabe et al, 1996). However; the presence
or even the role of these enzymes in the central nervous system has not yet been
elucidated.

In the present work we seek to elucidate the specific anatomical localization of
the disialic acid epitopes in the central nervous system and the expression of the
ST8Sia III gene involved in disialic acid transfer.

Based on the hypothesis that the diSia epitope is ubiquitously distributed in the
central nervous system and that its expression, along with the expression of the
enzyme ST8Sia III is differentially expressed along life, the objective of the present
work is to identify at a histological level the diSia epitope in different structures of the
mouse brain (cortex, hippocampus, olfactory bulb and cerebellum) and investigate at a
molecular level the differential expression of the α2,8-sialyltransferase III gene at
various stages along life.
RESULTS

Gene expression. Quantitative ST8Sia III gene expression on different brain regions was determined by Real Time PCR. No significant differences for the ST8Sia III gene were found in the hippocampus, olfactory bulb or cortex in any of the groups. However a significant decrease (p = 0.01, "t" test) was found in the senile cerebellum, (0.3480 ± 0.1803) compared to neonates (1 ± 0.1060) (Figure 1A).

In order to analyze if the down-regulation of ST8Sia III was related to alterations at the synaptic level, the gene expression of synaptophysin, a synaptic vesicle glycoprotein, was analyzed in the cerebellum at different stages (Figure 1B). Both, in the neonate group and senile animals, the expression of the gene was diminished compared to the adult animals (p < 0.01, F = 8.46 ANOVA between groups).

On the other hand, we observed that in the cerebellum of neonates the expression of the synaptophysin gene had an inverse correlation with that of the ST8Sia III gene (r = -0.95, p < 0.05). However, in adults and senile animals the correlation was direct and elevated (r = 0.84, p > 0.05; r = 0.83, p > 0.05), indicating some relation between the expression of the two genes.

We also studied the gene expression of disialyltransferases ST8Sia I and ST8Sia VI in the same structures. ST8Sia I mRNA showed high levels of expression in the hippocampus of neonates and decreased levels in adults and senile. In contrast, in the olfactory bulb the expression of the ST8Sia I gene was higher in the senile group compared to neonates and adults. We found very low levels of expression for the ST8Sia I gene in the cortex and cerebellum (Figure 1C). Regarding ST8Sia VI mRNA, we observed almost no expression for this gene in the neonate hippocampus but it was high in adults. In the olfactory bulb, cortex and cerebellum a gradual increase of ST8Sia VI mRNA was found from low levels in neonates to high levels in senile animals (Figure 1D).
The ST8Sia II and ST8Sia IV polysialyltransferase genes were also analyzed because they synthesize both Neu5Acα2→8Neu5Ac and polysialic acids epitopes. We found that ST8Sia II gene expression is constant in the cerebellum at all stages, whereas ST8Sia IV gene levels increase from neonates to adults and decrease again in the senile group (Figure 1 E-F).

Distribution of diSia epitope in the mouse brain. In concordance with molecular biology results, histological analysis revealed a similar pattern of expression for the diSia epitope, Neu5Acα2→8Neu5Acα2→3Gal recognized by the S2-566 antibody. No staining differences in the hippocampus, olfactory bulb or cortex were observed but there was an important decrease in diSia labeling in the senile cerebellum compared to neonates (Table I) (Figure 2 A-D). NB-DGJ-treated mice showed the same pattern of S2-566 immunolabeling as the non-treated mice, which suggests that this labeling corresponds to glycoproteins (Figure 2 D). This result is supported by the decreased labeling of GM1 observed in the whole brain of NB-DGJ treated mice, as compared to non-treated animals (Figure 2 F and G).

DISCUSSION

The sialidation of glycoproteins and glycolipids is important for central nervous system development and function (Tsuji, 1983; Hildebrandt et al, 1996; Rutishauser and Landmesser, 1996; Seki and Rutishauser, 1998). Although the role and distribution of polysialic acid have been investigated, those of the oligosialic structures, such as disialic and trisialic acids have not been fully examined. In this study we describe the distribution of the diSia epitope, Neu5Acα2→8Neu5Acα2→3Gal, and also the expression of the ST8Sia III gene. The results presented here suggest that the disialic acid epitopes recognized by S2-566 could be glycoproteins because after mice were
treated with NB-DGJ, a ganglioside synthesis inhibitor, a similar pattern and level of intensity of immunostaining were observed in the brain as the non-treated mice (Baek et al., 2008). Whereas, the synthesis of GM1 gangliosides were markedly inhibited in the brain of treated mice (see Figure 2 F and G). Nevertheless, further experiments are needed to identify the diSia-carrier glycoproteins in the mouse brain.

Consistent with the expression of 2,8-linked disialic acids in the hippocampus, olfactory bulb, cortex and cerebellum from neonates to adult animals, we show that the mentioned areas consistently express the sialyltransferase ST8Sia III mRNA, which transfers one sialic acid onto sialylated glycan acceptors.

Our results suggest a relation between the disialic epitope and the ST8Sia III enzyme, since when other disialyltransferases where studied (ST8Sia I and ST8Sia VI), both of these showed a distinct level in mRNA expression compared to disialic acid labeling.

Thus, at a transcriptional level, neural cells from different structures in neonates and adults generate 2,8-linked disialic acids at the cell surface. However, the cerebellum of senile animals shows a different pattern of both ST8Sia III transcriptional expression and of the corresponding glycoepitope (a significant decrease in the levels of expression of ST8Sia III and diSia epitopes). This result is very interesting; especially in relation to changes that ageing could produce in the cerebellum. Regarding the mechanism of sialidation, recent results show that patients with cerebellar ataxia present abnormalities in the metabolism of sialic acids, suggesting that the sialidation of key central nervous system proteins in the cerebellum is altered (Mochel et al., 2009). It is necessary to recognize that the mechanism/s related to cerebellum neurodegenerative illnesses could have a direct relation to the changes that might cause ageing. In this respect, we observed that ST8Sia III have equivalent levels of expression in the cerebellum of neonates and adults, with a gradual decrease until
the senility stage. However, these results merit future lines of research to relate neurodegenerative processes in the cerebellum caused by ageing and the mechanisms of sialidation.

It is interesting to link the decreased gene expression of sialyltransferase with a relative decrease of the synaptic capacity in senile animals. In this sense, synaptophysin was used for quantification of synapses (Calhoun et al, 1996). We analyzed the gene expression of synaptophysin at different stages in the cerebellum and in the senile group, a similar pattern and also a correlation of gene expression between the expression of the ST8Sia III gene and the synaptophysin gene. This correlation of both enzymes in the cerebellum of senile animals could indicate some role of disalic acids at the synaptic level.

In relation to the other structures of the central nervous system, the expression of ST8Sia I, ST8Sia II, ST8Sia IV and ST8Sia VI on one hand and, ST8Sia III on the other, present notable differences in gene expression: while the first enzymes show a remarkably heterogeneous pattern of expression at different stages of life, ST8Sia III remains with a constant expression during development with levels statistically equivalent between adult and neonates. This would suggest that while other enzymes have a variable role in vital development with an important expression in post-natal level, ST8Sia III remains constantly expressed, indicating an important functional role in all life stages.

In conclusion, the differential pattern of expression of the ST8Sia III gene and also of the disialic epitope that shows a clear down-regulation in the cerebellum of senile animals, merit future lines of research regarding the roles of disialic acids in normal aging and in cerebellar diseases.
MATERIALS AND METHODS

Animals and tissues

C57BL/6 mice of different stages were used: 5-days (Neonate), 4-months (Adult) and 10-months old (Senile).

Animals were raised in a temperature-controlled room (23°C) under a 12 hrs light: 12 hrs dark photoperiod with lights on at 7 hrs am and light intensity of approximately 250 lux. Food (Purina rodent Chow, Ralston Purina, St. Louis, MO) and water were provided ad libitum. This study was approved by our institution's animal care and use committee and following NIH guidelines.

Brains were extracted after decapitation under anesthesia. Hippocampus, olfactory bulb, cortex and cerebellum were obtained through microdissection by trained people according to bibliography (Meredith and Arbuthnott, 1993). In one group of animals (n = 6) RNA was extracted from the different tissues. In another equivalent group (n = 6), animals were anesthetized, and after brains were extracted, they were embedded in Cryoplast, frozen in dry ice and cut in cryostat. The slices were stained to observe the anatomical localization of diSia by immunohistochemistry.

Real Time PCR

Reverse transcription was performed on 2 µg of total RNA, previously treated with RQ1 RNase-free DNase (Promega, Madison, USA) to eliminate possible contamination of genomic DNA. One microgram of treated RNA was used as template in a 20µl volume cDNA synthesis reaction. Complementary DNA (cDNA) was synthesized using RT (ImpromII; Promega, Madison, WI) with oligo(dT) (Promega, Madison, WI) following the manufacturer’s instructions. Quantitative real-time PCR was performed using SYBR Green (Invitrogen), Platinum Taq Polymerase (Invitrogen) and LightCycler 2.0 Instrument (Roche Applied Science).

The protocol used was the following: 10 minutes at 94°C and 40 cycles of 45 seconds at 94°C, 30 seconds at the melting temperature (58°C) and 10 seconds at
72°C. In all cases, similar results were obtained when PCR was performed using cDNA as sample. The GAPDH gene was used as housekeeping gene. The primers for ST8Sia I, ST8Sia II, ST8Sia III, ST8Sia IV, ST8Sia VI, synaptophysin and GAPDH genes, were designed using the Primer3 program. Primers (Table II) were designed according to the Gene Bank database.

The expression of mouse GAPDH was used to standardize gene expression levels. Each sample was run in duplicate. Control experiments without template cDNA revealed no unspecific amplification. To verify the identity of amplified DNAs, the size of the PCR products were checked on agarose gel. Melting curves of all samples were always performed as a control of specificity.

Analysis of relative gene expression was performed using the Standard Curves method (Peinnequin et al, 2004; Bustin, 2000).

**Immunofluorescence Microscopy**

For immunofluorescence, the slides with the tissues were fixed with 4% paraformaldehyde at 25°C for 5 min, followed by washing with Phosphate Buffered Saline at pH=7,2 (PBS). The samples were then blocked with 10% Powerblock solution (Bio Genex, Inc.), and incubated with the primary antibodies S2-566 (Seikagaku Co., Japan) 10 g/ml or at 4 °C for 20 h. After washing with PBS, the slides were incubated with biotinilated-IgM (Vector Laboratories, INC. Burlingame, U.S.A.) secondary antibody at 25°C for 60 min., washed with PBS and incubated with Texas Red (Vector Laboratories, INC. Burlingame, U.S.A.) and then the nucleus was stained with Hoescht.

After washing with PBS, the samples were observed under a fluorescent microscope (Nikon eclipse E400). In order to evaluate if the staining corresponded to gangliosides or glycoproteins, a group of animals (n= 4) were treated with N-butyldeoxygalactonojirimycin (NB-DGJ), a drug that specifically inhibits the glucosylceramide synthase. NB-DGJ was purchased from Toronto Research Chemicals, Inc. (North York, Ontario, Canada).
NB-DGJ solutions were prepared in sterile saline to yield a final concentration of 0.2 mg/μl. Postnatal C57BL/6 mice were injected daily intraperitoneally from p-0 to p-6 with either vehicle (0.9% saline) or NB-DGJ at 600 mg/kg body weight. Injections were performed using a Hamilton syringe (30 gauge), and volumes ranged from 10 to 25 μl/mouse (Baek et al, 2008).

Tissues were obtained as described above. Brains from NB-DGJ treated vehicle or non treated mice (Neonatal, Adult and Senile), were separated from the skull and immersed in Cryoplast (Biopack, Argentina). The tissues were frozen on dry ice, stored at -80°C and sectioned on a cryostat (Microm HM 550) at 14 μm. To measure the density, we used the ImageJ software. Ten points were randomly measured in each photo and the mean and standard deviation on each sample group and positive control were determined.

As a positive control, a Neuro2A cell culture was immunostained for s2-566 antibody, four days after treatment with retinoic acid, in accordance to Sato et al. (Sato et al, 2002) (Figure 2).

NB-DGJ treated mice were analyzed for GM1 composition with anti-cholera toxin-B subunit conjugated with Alexa 555, according to previous work (Iglesias Bartolomé, 2009).

Statistical analysis

To assess quantitative differences among treated animals or controls regarding different variables, a software package was utilized (Glantz, 2005).

All molecular biology and immunohistochemistry results were controlled with adequate positive and negative controls.
FUNDING
